## ABSTRACT

Physical vapor deposition can prepare organic glasses with high kinetic stability. When heated, these glassy solids slowly transform into supercooled liquid in a process known as rejuvenation. In this study, we anneal vapor-deposited glasses of methyl-m-toluate for 6 h at 0.98 $T_g$  to observe rejuvenation using dielectric spectroscopy. Glasses of moderate stability exhibited partial or full rejuvenation in 6 h. For highly stable glasses, prepared at substrate temperatures of 0.85 $T_g$  and 0.80 $T_g$ , the 6 h annealing time is ~2% of the estimated transformation time, and no change in the onset temperature for the  $\alpha$  relaxation process was observed, as expected. Surprisingly, for these highly stable glasses, annealing resulted in significant increases in the storage component of the dielectric susceptibility, without corresponding increases in the loss component. These changes are interpreted to indicate that short-term annealing rejuvenates a high frequency relaxation (e.g., the boson peak) within the stable glass. We compare these results to computer simulations of the rejuvenation of highly stable glasses generated by using the swap Monte Carlo algorithm. The *in silico* glasses, in contrast to the experiment, show no evidence of rejuvenation within the stable glass at times shorter than the alpha relaxation process.

## I. INTRODUCTION

Glasses have many applications in modern life, well beyond windowpanes and eyeglasses. For example, the layers of organic emitters in organic light emitting diode (OLED) screens found in most modern smart phones are glasses of organic semiconductors.<sup>1</sup> Many applications that require optical transparency, such as optical fibers, or compositional flexibility, such as organic electronics, also use glassy materials.<sup>2–4</sup> In addition, there has been much interest in the potential applications of glasses of metal mixtures, whose high elasticity and high strength, as well as their resistance to corrosion, make them intriguing prospects for many advanced technological applications.<sup>5–9</sup>

Glassy materials have inherent nonequilibrium and have properties that depend upon their method of preparation. Glasses are typically formed by cooling a liquid to temperatures below its melting point, into a metastable state called the supercooled liquid, and then continuing to cool until the molecules or atoms no longer have enough mobility to maintain the liquid's properties (i.e., density and enthalpy). The temperature at which this change occurs is referred to as the glass transition temperature ( $T_g$ ), and below this point, the liquid is considered to have formed a glass.<sup>2,10</sup> Cooling may be conducted at different rates. Both cooling more slowly and cooling followed by isothermal annealing lead to denser glasses with lower enthalpy and improved physical properties, such as elastic modulus and thermal stability.<sup>11–17</sup> However,

given the range of practical cooling rates and annealing times, only marginal improvements in properties can be attained by using this approach.<sup>2,18–21</sup>

In contrast to liquid cooling, physical vapor deposition (PVD) provides a practical approach to access low enthalpy and high stability glass states.<sup>22</sup> This method of forming a glass involves the deposition of molecules out of the gas phase onto a temperature-controlled substrate. When the substrate is held at temperatures somewhat below  $T_g$ , the enhanced mobility of the molecules at the free surface allows fast equilibration toward the liquid at the substrate temperature.<sup>23–30</sup> For higher deposition temperatures and slower deposition rates, the metastable supercooled liquid seems to be reached, while lower deposition temperatures and faster deposition rates create glasses with high density and low enthalpy that are distinct from the supercooled liquid.<sup>26,31,32</sup> A major advantage of the PVD technique is that it forms glasses with low enthalpy and high stability on a timescale of minutes, rather than the many years it would take to reach such low-energy states through liquid-cooling.<sup>18,21,33</sup> PVD is thus an advanced materials processing technique that rapidly offers glasses with significant technological advantage.

Stable PVD glasses uniquely allow systematic observation of the process of rejuvenation for samples with low enthalpy and high stability. The primary structural relaxation (also called the  $\alpha$  relaxation) in these glasses is shifted to extremely long times, such that it is impossible to directly observe. When stable glasses are heated above  $T_g$ , the  $\alpha$  relaxation process is slow to grow back in, as indicated by an elevated onset temperature ( $T_{ons}$ ) where the glass recovers to the liquid state.<sup>33,34</sup> The mechanism of this rejuvenation of the primary relaxation process for stable glasses is of particular interest, as it gives insight into the structure and dynamics of these low-energy states. A previous work has shown that these transformations have several unique features. A stable PVD film heated above  $T_g$  initiates a front of supercooled liquid that grows through the film from the free surface; surface initiation results from enhanced mobility at the surface relative to the bulk.<sup>35–37</sup> For thick films (or when the front mechanism is suppressed by a capping layer<sup>38</sup>), a bulk mechanism also takes place. This involves nucleation of “bubbles” of liquid within the rigid matrix of the dense stable glass. These liquid regions then grow with time until the whole film has transformed.<sup>37–42</sup> These rejuvenation features are generic signatures of highly stable glasses (rather than PVD glasses in particular) as they have all been observed in computer simulations that utilize highly equilibrated configurations (not generated by deposition).<sup>39,43</sup> Of particular relevance are simulations that use the swap Monte Carlo algorithm<sup>44</sup> to generate ultrastable amorphous packings that rival the stability of experimental PVD glasses.<sup>45,46</sup>

Highly stable PVD glasses also show partial suppression of relaxation processes that occur below  $T_g$ . Examples include the suppression of the Johari–Goldstein beta relaxation<sup>34,45,47</sup> as well as of other intramolecular relaxation processes<sup>42,48</sup> and also a reduction in the number of quantum tunneling two-level systems.<sup>49,50</sup> The high frequency boson peak, which is a relaxation process present in all disordered materials,<sup>51–55</sup> is also suppressed in stable glasses.<sup>56–58</sup> This process appears as an excess in the vibrational density of states (VDOS) of the glass relative to that of the Debye crystal and can be observed in the low-temperature heat capacity as well as in measurements such as neutron and Brillouin light scattering. The boson peak

also appears in dielectric spectra between 100 and 1000 GHz.<sup>59</sup> There are many physical pictures that have been used to explain the origin of the boson peak, ranging from phonon modes<sup>52,54,60</sup> to relaxation of clusters of locally preferred structures<sup>51</sup> within the glass, without any strong consensus. Regardless of the origin, it has been observed that increasing the density of the glass, either through increasing the pressure<sup>61,62</sup> or by decreasing the cooling rate<sup>63</sup> or otherwise forming a more stable glass,<sup>64</sup> results in a decrease in the boson peak intensity.

In contrast to previous studies of the rejuvenation of stable PVD glasses above  $T_g$ , this work seeks to understand rejuvenation below  $T_g$ , with a focus on the initial stages of rejuvenation. We quantify rejuvenation by examining changes in the dielectric susceptibility for vapor deposited films of methyl-m-toluene (MMT,  $T_g = 170$  K) annealed at  $0.98T_g$  for up to 6 h. While less stable glasses of MMT completely rejuvenate on this timescale, the recovery of the  $\alpha$  peak on heating of the most stable films is unaffected by this annealing. Surprisingly, the most stable glasses show an increase in the storage component of dielectric susceptibility during annealing, suggesting that the boson peak (at frequencies above the experimental range) is substantially recovering even though the annealing time is only ~2% of the time required to fully rejuvenate these glasses. This appears to indicate a “softening” of the stable glass long before it transforms into the supercooled liquid, potentially related to the softening reported previously.<sup>65</sup>

Given the surprising nature of the experimental observations, we make careful comparisons with swap Monte Carlo computer simulations on two-dimensional polydisperse systems. In a procedure analogous to the experiments, the rejuvenation of a highly stable glass has been observed after a temperature upjump. A previous work has shown that these *in silico* glasses rejuvenate in a manner similar to the most stable experimental glasses (prepared by PVD).<sup>39,43</sup> However, here, we find no feature in the computer simulations that can be associated with the experimentally observed increase in the storage component of the dielectric response. That is, the computer simulations show no evidence of softening of the stable glass, prior to its transformation to the supercooled liquid. We present some speculative ideas for this contrast between experiments and computer simulations.

## II. METHODS

### A. Experiments

Liquid MMT of 98% purity was purchased from Alfa Aesar and the material was used as received. Films of MMT were vapor-deposited onto a temperature-controlled substrate within a custom-built vacuum deposition chamber, with typical base pressure lower than  $10^{-9}$  Torr. Glassy films were prepared using substrate temperatures below  $T_g$ , specifically  $138.2$  K ( $0.80T_g$ ), forming the glass with the highest stability),  $143.2$  K ( $0.85T_g$ ),  $153.2$  K ( $0.90T_g$ ), and  $161.2$  K ( $0.95T_g$ ), forming the glass with the lowest stability). The typical thickness of these films was  $5\ \mu\text{m}$  with a typical rate of deposition about  $1.8 \pm 0.5\ \text{nm/s}$ . Variations in deposition rate did not measurably affect the stability of the prepared films. The procedure for determination of the deposition rate, and the thickness of the resulting films, is discussed in the [supplementary material](#). Corresponding liquid-cooled glasses were generated by

transforming the stable samples by heating above  $T_g$  and then cooling at 5 K/min.

To allow the dielectric measurements to be conducted *in situ*, the film was deposited onto an interdigitated electrode (IDE), IME 1025.3-FD-Pt-U manufactured by ABTECH Scientific, Inc. This IDE has two pairs of platinum fingers that were microlithographically patterned in the lift-off method onto a borosilicate glass substrate. Each pair of electrodes consists of a total of 50 interdigitated fingers that are 10  $\mu\text{m}$  wide and spaced 10  $\mu\text{m}$  apart, leading to a geometric capacitance of 0.65 pF. One of these pairs of electrodes was exposed to the vapor deposition and formed a film of deposited material, while the other is enclosed to prevent deposition. The temperature of the substrate was measured by using a three-wire resistance temperature detector (RTD) and controlled with a heater connected to an Omron temperature controller.

To measure the dielectric susceptibility of the film, a Solartron SI-1260 applies an alternating voltage ( $V_{\text{rms}} = 2.9$  V) across the electrodes; the resulting current for each pair of electrodes is then measured using two transimpedance amplifiers.<sup>66,67</sup> The relationship between current and voltage gives the experimental complex impedance according to  $Z^* = \frac{V^*}{I^*}$ . This impedance is converted to the dielectric susceptibility ( $\chi^* = \chi' - i\chi''$ ) as described previously.<sup>68</sup>

We used two different methods to account for the substantial temperature-dependent contribution to the susceptibility values from the borosilicate substrate of the IDE. For isothermal measurements, a constant-value background-subtraction method was employed. The values for each experiment were taken as the average of the near-constant baseline, as measured for 10 min at the annealing temperature before film deposition. This constant value was then subtracted from the measured real and imaginary susceptibilities for each frequency, as obtained during annealing. For experiments where temperature was not held constant, a two-channel subtraction method was instead employed, making use of the second, covered pair of electrodes to provide the substrate contribution at each temperature.

Two types of isothermal annealing experiments were performed. The first focused on monitoring the dielectric susceptibility at a pair of frequencies, 20 Hz and either 610 Hz or 20 kHz, during annealing at 167.2 K (0.98 $T_g$ ). These frequencies were chosen to minimize the contribution of noise from the system and surroundings and are located in the portions of the spectral window where the high frequency wing of the  $\alpha$  peak and the low frequency wing of the beta peak overlap (20 Hz), or in the high frequency wing of the beta peak (610 Hz or 20 kHz). The second type of experiment took full spectra ( $10^5$ – $10^6$  Hz, with eight points per decade spaced logarithmically) during the same annealing protocols. This second measurement protocol sacrifices time resolution for more detail on the relaxation processes occurring during the annealing since each spectrum took about 10 min to collect.

After isothermal annealing, the glassy film was transformed into the supercooled liquid by heating at 5 K/min. The kinetic stability of the film was assessed using the onset temperature on heating. The onset temperature, which is defined to be representative of the bulk transformation process for these thick PVD films, is determined by fitting a line to the loss component at low temperatures and then finding its intersection with a line fitted to the final approach to the supercooled liquid curve, as shown in the [supplementary material](#), Fig. 3.

The transformation of the corresponding liquid-cooled film, formed by cooling the supercooled liquid at 5 K/min, was observed in the same manner. This allowed us to confirm that our temperature calibration was consistent within 0.5 K and that the film showed no loss of signal due to crystallization. Crystallization was not observed if the film remained below roughly 195 K.

We fit data from these experiments to Kohlrausch-Williams-Watts (KWW) functions in order to parameterize the shape and timescale of changes observed. This function has the form  $\frac{(T_{\text{ons}}(t) - T_{\text{ons},\infty})}{(T_{\text{ons}}(0) - T_{\text{ons},\infty})} = e^{-(t/\tau_{\text{KWW}})^\beta}$ , where  $t$  is time,  $T_{\text{ons}}(t)$  is the onset temperature at time  $t$ ,  $T_{\text{ons}}(0)$  is the onset temperature of the unannealed sample,  $T_{\text{ons},\infty}$  is the equilibrium onset temperature at the annealing temperature,  $\beta$  is the stretching exponent describing the deviation from an exponential form, and  $\tau_{\text{KWW}}$  is the characteristic timescale.

## B. Simulations

Following a previous work,<sup>39</sup> we performed molecular dynamics (MD) simulations on a two-dimensional size-polydisperse mixture composed of soft repulsive spheres. We refer to this publication for details regarding the particle size distribution and the pairwise potential between particles. We employ reduced units based on the mass  $m$  of the particles and the energy scale  $\varepsilon$  of the pair potential to express timescales in units of the microscopic time  $\tau_{\text{LJ}} = \sqrt{m/\varepsilon}$ , where  $\sigma$  is the unit length defined as the average particle diameter. We use a system composed of  $N = 64\,000$  particles in a periodic simulation box. We studied the rejuvenation of ultrastable systems prepared using the swap Monte Carlo algorithm. The stability of the system is encoded in the preparation temperature  $T_i$  used to create these configurations. Here, we used the most stable configurations created at  $T_i = 0.035 \sim T_g/2$ . Rejuvenation is induced by suddenly heating the system to a higher temperature  $T_a = 0.1\text{--}1.4T_g$ , keeping the pressure constant. Compared to the experiments, the annealing temperature is larger, as rejuvenation at lower  $T_a$  is too slow to be observable in our numerical time window.

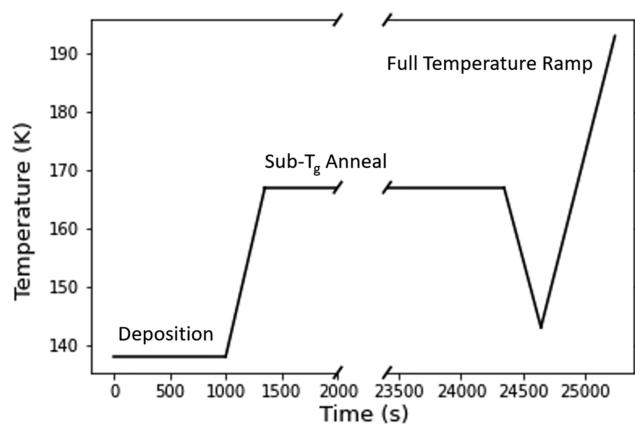

At this  $T_a$ , the transformation time is larger than  $10^7$ , and thus, we can easily analyze the behavior of the system at times much before complete rejuvenation, in analogy with the experiments. The dynamics of the system is analyzed using the mean-squared displacements (MSD) of the particles,

$$\Delta^2(t_w, t_w + t) = \frac{1}{N} \sum_i^N |r_i(t + t_w) - r_i(t_w)|^2, \quad (1)$$

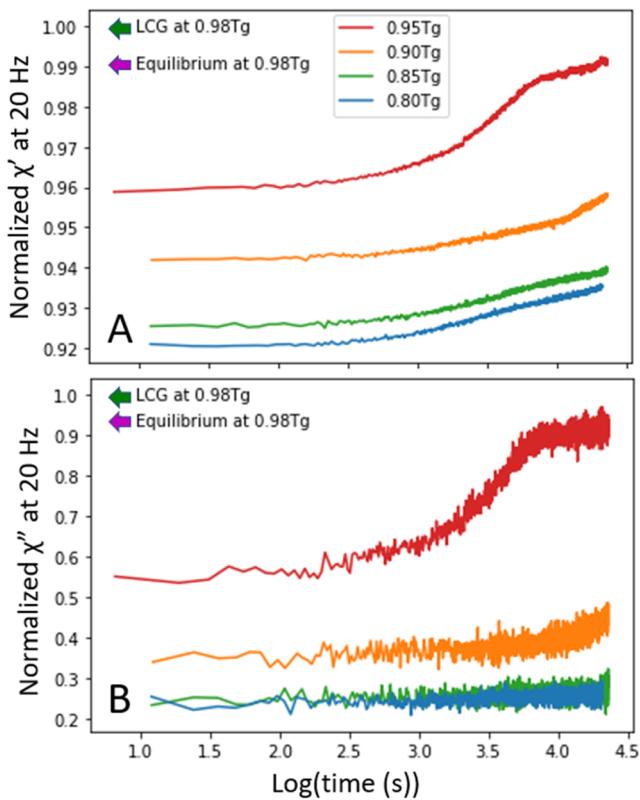

where  $r_i(t)$  is the position of the particle  $i$  at time  $t$  and the rejuvenation process starts at  $t_w = 0$ . By systematically varying  $t_w$  and  $t$  in the MSD, we can resolve the dynamics of the system over a broad time window, at various stages of the rejuvenation process.

## III. EXPERIMENTAL RESULTS

In these experiments, we observed changes in the dielectric response of vapor-deposited glasses of MMT during and after 6 h of isothermal annealing. Each individual experiment consists of three parts, as shown in [Fig. 1](#): the deposition, during which the substrate temperature is constant, controlling the stability of the deposited film; the sub- $T_g$  annealing, conducted at 0.98 $T_g$  (167.2 K) to allow

**FIG. 1.** Temperature profile schematic of a typical experiment on a vapor-deposited glass of MMT, highlighting the three important stages of the experiment: deposition at temperatures below  $T_g$ , annealing at  $0.98T_g$ , and finally heating above  $T_g$  to observe the onset temperature characterizing the return of the film to equilibrium.

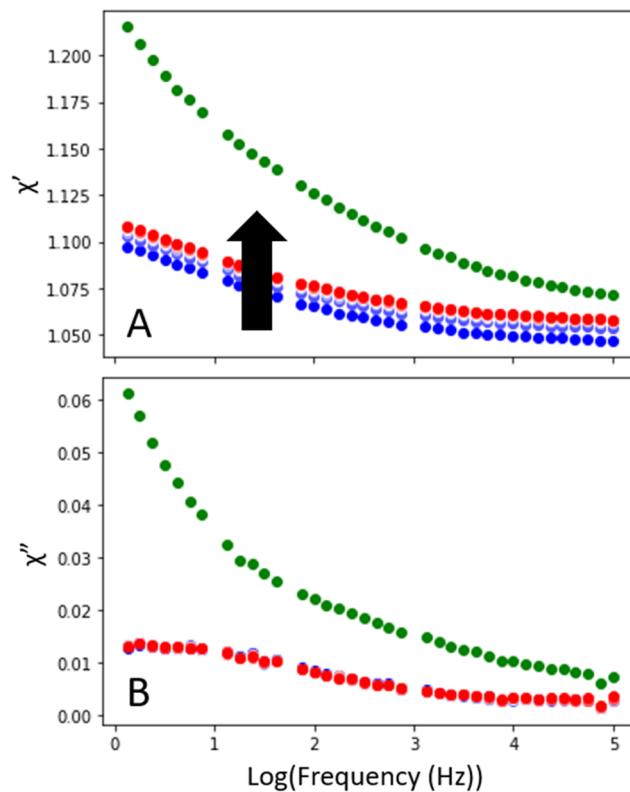

**FIG. 2.** Normalized changes in  $\chi'$  [storage component, (a)] and  $\chi''$  [loss component, (b)] measured at 20 Hz, as a function of annealing time at  $0.98T_g$  for PVD glasses deposited at different substrate temperatures. To account for slight differences in sample thickness, these values are normalized by dividing by the value of the same quantity measured for the corresponding liquid-cooled glass at  $0.98T_g$  for each film, defined at 1 as indicated by the green arrows. The value (normalized in the same way) for a film aged to equilibrium at  $0.98T_g$  is represented by the magenta arrow in each plot.

the film to partly or completely rejuvenate; and the full heating above  $T_g$ , which reads out the effect of the annealing protocol on the  $\alpha$  relaxation process based on the onset temperature. In the following, we first discuss the results observed during the annealing step and then separately results from the transformation step.

The observed dielectric property used here is the complex dielectric susceptibility,  $\chi^* = \chi' - i\chi''$ . This is similar to the more commonly used dielectric permittivity,  $\epsilon^*$ , with the difference being that the real component starts from a value of zero when there is no contribution from a sample, compared to  $\epsilon'$ , which starts at a value of 1.  $\chi^*$  is more convenient for our discussion of relative changes of the dielectric response with time.

### A. Isothermal annealing below $T_g$

During annealing at  $0.98T_g$ , the vapor-deposited glasses of MMT with different stabilities responded qualitatively differently, as shown in Fig. 2. For the somewhat stable films (those deposited at  $0.95T_g$ ), the glasses rejuvenate completely during annealing: their storage and loss increase to a new steady state, as expected for a

**FIG. 3.** Storage (a) and loss (b) components of a  $0.80T_g$  MMT glass during annealing at  $0.98T_g$ . To decrease noise, the 34 spectra acquired were averaged in groups of 5 (with one group of 4). The earliest spectrum is shown in blue, while the last is shown in red, with the gradient between the two representing the progression of annealing time. Selected frequencies were removed from all spectra due to noise issues. The spectrum measured at the same temperature for the corresponding liquid-cooled glass of this same film is shown in green. The broad peak centered near 10 Hz is the  $\beta$  relaxation process (the amplitude is suppressed in the PVD glass).

film that reaches equilibrium at  $0.98T_g$ . To confirm that the final steady state is the equilibrium state, we aged a liquid-cooled glass to equilibrium at  $0.98T_g$ . The values at the end of that experiment (indicated by the magenta arrows and discussed in more detail in the [supplementary material](#)) are in good agreement with the final steady state of the deep red curves shown in [Fig. 2](#). The shape of this relaxation, which fits to a KWW function with exponent  $\beta = 1.1$ , as shown in the [supplementary material](#) Fig. 7, is consistent with a decrease in density toward equilibrium after a temperature upjump.<sup>69</sup> As we discuss in the following, an equilibration time of  $\sim 10^4$  s is reasonable for a glass of this stability at this annealing temperature.

Films deposited at  $0.90T_g$  show partial rejuvenation during annealing at  $0.98T_g$ , as seen by an increase in the storage component and the smaller increase in loss component. If this film had reached equilibrium during annealing, the final dielectric observables would have matched the final values attained for the  $0.95T_g$  glass.

In contrast to these less stable films, the most stable glasses are those deposited at  $0.85T_g$  and  $0.80T_g$ , which show increases in the real component of dielectric susceptibility only [[Fig. 2\(a\)](#)], with no appreciable change in the loss component [[Fig. 2\(b\)](#)]. In particular, in 6 h of annealing, the real component of the most stable films increases by almost 20% of the difference between the initial stable glass and the final equilibrium state at  $0.98T_g$ . While [Fig. 2](#) shows the dielectric results obtained at 20 Hz, similar results were obtained at two other frequencies (610 Hz and 20 kHz), as shown in the [supplementary material](#), [Fig. 8](#).

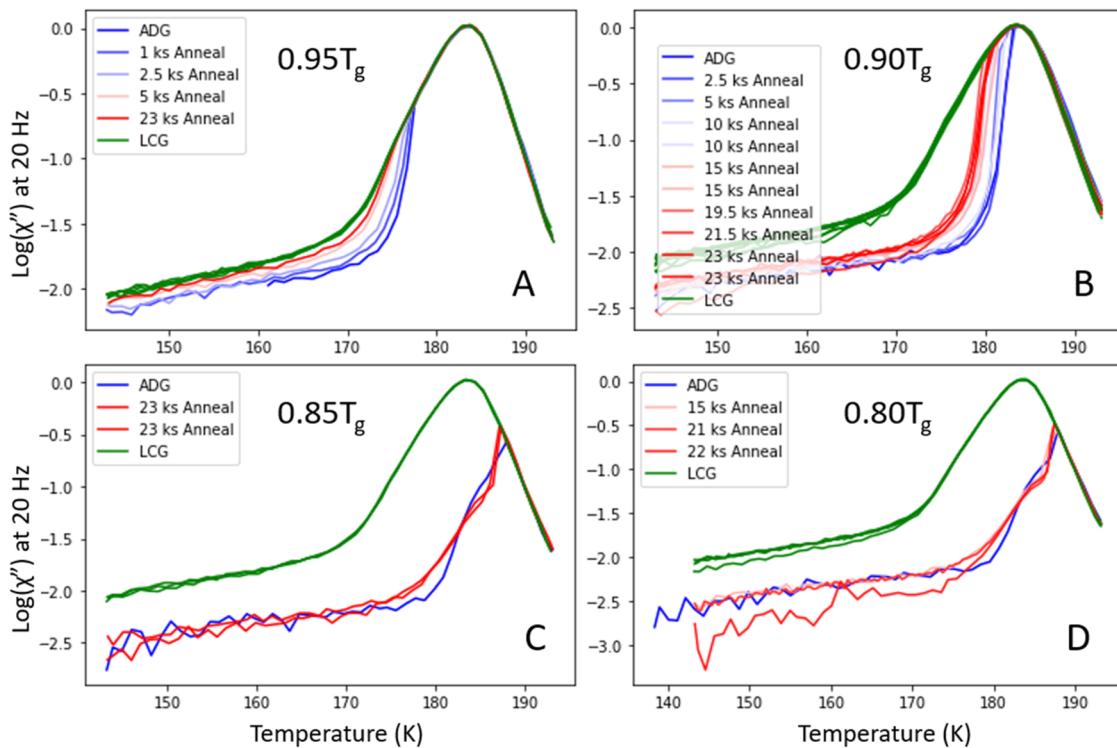

The observation that the most stable PVD glasses show an appreciable increase in the storage component without any apparent change in the loss was notable and surprising. To investigate this further, we conducted equivalent experiments on the most stable glasses ( $0.80T_g$ ), taking full dielectric susceptibility spectra during 6 h of annealing to more fully understand the observed features in the single-frequency experiments. As shown in [Fig. 3](#), the increase in the storage component is uniform across the entire spectrum. The data shown in [Fig. 3](#) are fully consistent with those shown in [Fig. 2](#).

We return to the interpretation of these results in Sec. IV.

## B. Temperature ramping into the supercooled liquid

A second way to examine the effect of the annealing on the state of the glass is to measure the onset temperature upon heating after annealing has been completed. A high onset temperature is an indicator of high kinetic stability in the glass and correlates well with a decrease in enthalpy.<sup>32,70,71</sup> Here, we transform the deposited films after different annealing times to look for changes in the onset temperature as a second way to quantify the extent of rejuvenation. The temperature ramping experiments revealed a simple trend as a function of annealing time and glass stability.

The films deposited at  $0.95T_g$  rejuvenate completely during annealing at  $0.98T_g$ , as shown in [Fig. 4\(a\)](#). The as-deposited glass has a low value of  $\chi''$  until the onset of the transformation into

**FIG. 4.** Normalized values of  $\chi''$  on heating (5 K/min) for MMT glasses deposited at  $0.95T_g$  (a),  $0.90T_g$  (b),  $0.85T_g$  (c), and  $0.80T_g$  (d). The unannealed deposited glass is indicated by the darkest blue, while the film with the longest annealing time is indicated by the darkest red. The corresponding heating curves for the liquid cooled films associated with each deposition are indicated by green for comparison.

the supercooled liquid ( $T_{\text{ons}} \approx 174$  K). The sample completely transforms within a few Kelvin and joins the equilibrium supercooled liquid response at about 177 K. The large peak near 183 K is the  $\alpha$  relaxation process for the supercooled liquid measured at 20 Hz. Annealing at  $0.98T_g$  systematically reduces  $T_{\text{ons}}$ , and about 5 ks of annealing completes the transformation, in agreement with Fig. 2.

To facilitate later discussion, the evolution of  $T_{\text{ons}}$  with annealing time is shown in Fig. 5 for MMT glasses with a range of initial stabilities. The journey to equilibrium for the  $0.95T_g$  film value occurs on the timescale of a few thousand seconds at  $0.98T_g$ , as shown in Fig. 4(a). Since  $\tau_\alpha$  at  $0.98T_g$  is on the order of 1000 s [based on a Vogel–Fulcher–Tammann (VFT) extrapolation of literature data<sup>72</sup>] and as this is not a particularly stable glass, this transformation time is expected.

Figure 4(b) shows the evolution of the  $0.90T_g$  glasses during annealing at  $0.98T_g$ . These glasses show only partial rejuvenation over 23 ks, with a gradual decrease in the onset temperature during annealing. This is consistent with the results shown in Fig. 2, which also indicated an only partial rejuvenation. Figure 5 shows that the onset temperature shifts less than half of the way toward equilibrium over 23 ks.

Finally, the most stable MMT glasses [deposited at  $0.85T_g$  shown in Fig. 4(c), deposited at  $0.80T_g$  shown in Fig. 4(d)] show very little or no change in the onset temperature due to annealing, even at the longest annealing times. These results, shown in Fig. 5, are consistent with the picture that the re-equilibration of the  $\alpha$  process in these films has barely begun in 23 ks or not even started. Based upon measurements over a range of annealing temperatures, we estimate that the time required to equilibrate the  $0.80T_g$  sample at  $0.98T_g$  is roughly  $10^6$  s (see the supplementary material, Fig. 9). The observation that MMT glasses deposited at  $0.80T_g$  and  $0.85T_g$  have high kinetic stability is consistent with previous experiments.<sup>34,37,73</sup>

#### IV. DISCUSSION AND COMPARISON WITH SIMULATIONS

We have isothermally annealed PVD glasses of MMT at  $0.98T_g$  for up to 23 ks. Films thicker than 3  $\mu\text{m}$  were used in these experiments in order to access the bulk dynamics rather than any effects of the free surface, such as the transformation fronts observed in thinner films. We have characterized the rejuvenation of these glasses in two ways: (1) changes in the dielectric susceptibility during annealing (Figs. 2 and 3) and (2) changes in the temperature-induced transformation brought about by annealing (Figs. 4 and 5). For the two least stable glasses (deposited at  $0.95T_g$  and  $0.90T_g$ ), the results from the two methods of characterization are easily and consistently interpreted: the sample deposited at  $0.95T_g$  completely rejuvenates during 23 ks of annealing and the sample deposited at  $0.90T_g$  partially rejuvenates.

On the other hand, the results from the two methods of characterization are not easily understood for the two most stable MMT glasses (deposited at  $0.85T_g$  and  $0.80T_g$ ). The results obtained during temperature ramping show essentially no rejuvenation of the  $\alpha$  process as a result of annealing at  $0.98T_g$ , while  $\chi'$  recovers ~20% during annealing, relative to a fully rejuvenated sample. How does  $\chi'$  recover significantly without a significant change in the  $\alpha$  process? In addition, how does  $\chi''$  remain constant while  $\chi'$  is significantly changing?

#### A. Recovery of the boson peak

The increase in  $\chi'$  without an increase in  $\chi''$  at the same frequency, as shown for the most stable glasses in Figs. 2 and 3, indicates a change in the intensity of some process taking place at frequencies higher than our spectral window. This conclusion follows from the Kramers–Kronig relations, and we show this idea schematically in Fig. 6. We have speculatively identified this process as the boson peak, which is universal to all amorphous materials.<sup>51–55</sup> Despite our inability to directly observe the boson peak in this work, it is reasonable to suppose that the boson peak was suppressed in the original stable glass relative to a rejuvenated sample. This idea is supported by previous observations of the boson peak suppression in stable PVD glasses,<sup>49,58</sup> and is further consistent with the observation that glasses of higher density (formed through pressurization) and glasses of higher stability (formed through slower cooling) also have suppressed boson peak intensities.<sup>61–64</sup>

Based on the increase in the storage component during annealing (Fig. 2), we can estimate the extent of the boson peak's recovery for the most stable MMT glasses. We estimate the contribution of the boson peak to the dielectric susceptibility based on very high frequency dielectric measurements performed on another small organic molecular glass-former, glycerol;<sup>59</sup> this estimate is reflected in the green “rejuvenated” spectra shown in Fig. 6. Next, we account for the expected suppression of the boson peak in the stable glass. Based on the decrease in the height of the boson peak observed for stable PVD glasses of indomethacin,<sup>49</sup> we estimate that the height of the boson peak for a stable glass of MMT is 34% less than the height of the rejuvenated sample. This suppressed boson peak is depicted by the blue “stable” spectra shown in Fig. 6. This is a reasonable extent of suppression, as lowering the cooling rate for organic glasses has been previously observed to result in a boson peak suppression of

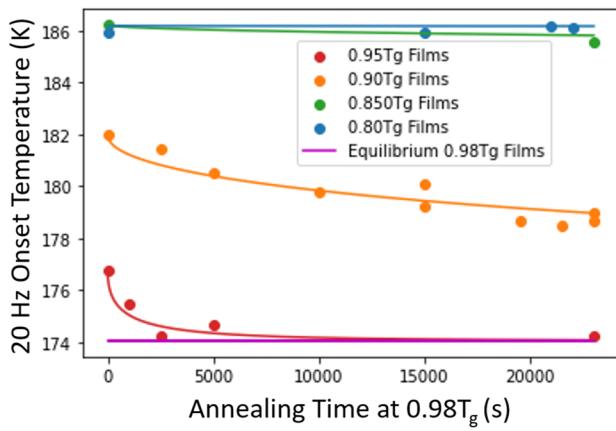

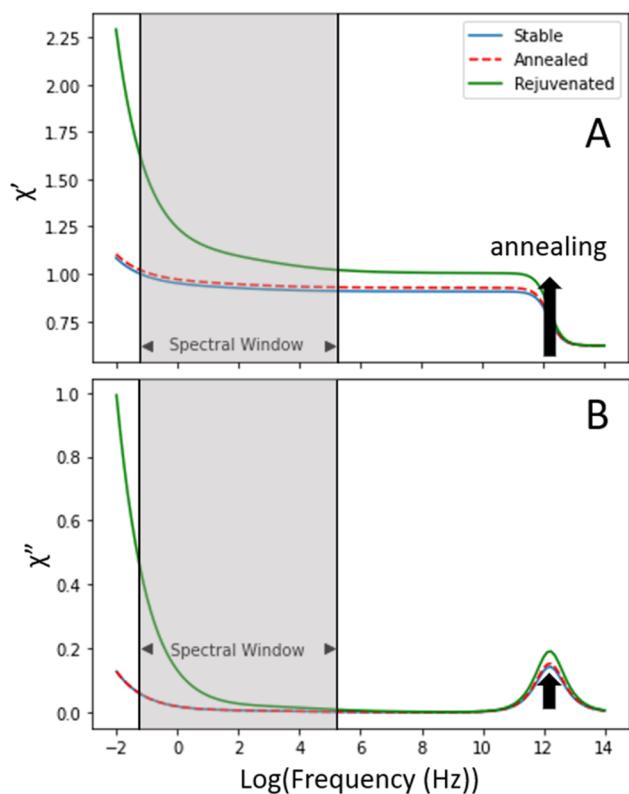

FIG. 5. Onset temperature as a function of annealing time at  $0.98T_g$  for MMT glasses of different stabilities. The onset temperature of a liquid-cooled glass that had been aged to equilibrium at  $0.98T_g$  is represented by the magenta line. For each deposition temperature, the evolution of the onset temperature with annealing time was fitted to a KWW function, represented by the solid lines.

**FIG. 6.** Simulated dielectric response of stable, annealed, and rejuvenated glasses of MMT. The blue spectra represent the stable glass with a suppressed boson peak. In this scenario, a partial recovery of the boson peak leads to an increase in  $\chi'$  without an increase in  $\chi''$ , as shown in Fig. 2.

7%;<sup>63</sup> we expect a much larger effect for PVD glasses due to their much lower fictive temperatures.

Using these values, we can recreate the 2% increase in the magnitude of  $\chi'$  observed at 20 Hz for the longest annealing time for the most stable glass (shown in Fig. 2) as indicated by the red-dashed “annealed” spectra shown in Fig. 6. The annealed glass spectra have a boson peak intensity that has increased by 7% relative to the stable glass value. Stated another way, when the boson peak recovers 20% of the way to its value in a fresh liquid-cooled glass, the value of  $\chi'$  also recovers 20% of the way to its rejuvenated value. According to this scenario, in our frequency range, such a change in  $\chi'$  would occur with negligible change in  $\chi''$ , consistent with our experimental result.

We expect that this explanation for the increase in  $\chi'$  without an increase in  $\chi''$  (over the frequency window from 1–10<sup>5</sup> Hz) is basically correct. We note that *any process* (not necessarily the boson peak) occurring at a frequency greater than 10<sup>5</sup> Hz would be a possible candidate for the behavior of  $\chi'$  and  $\chi''$ . However, this explanation leads to a new question: why would the boson peak (or another high frequency process) recover substantially in  $\sim 10^4$  s at  $0.98T_g$  when full rejuvenation requires a much longer time, as indicated by the negligible change in  $T_{\text{ons}}$  and the estimated rejuvenation time of  $\sim 10^6$  s (supplementary material Fig. 8)?

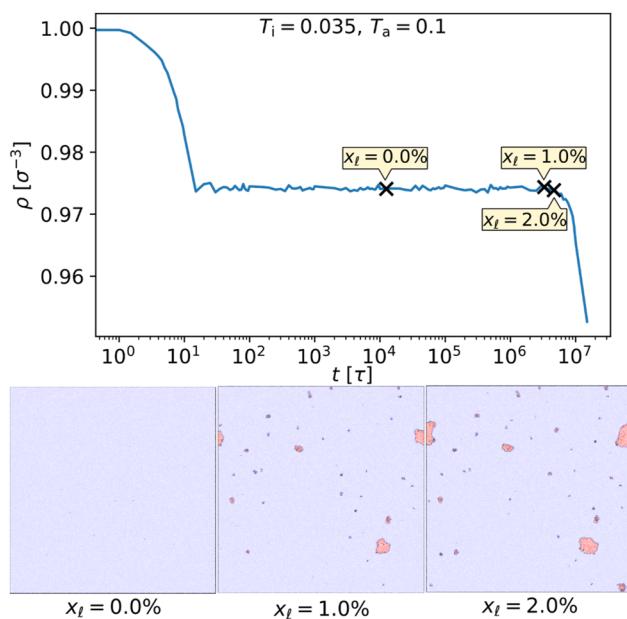

Our observations have some elements in common with a previously reported “softening” mechanism in the transformation of stable PVD glasses annealed above  $T_g$ ,<sup>41,65</sup> as reported by Vilacosta *et al.* These authors performed fast-scanning nanocalorimetry experiments on stable glasses of an organic semiconductor. Thin films of the stable glass were capped by a glass with higher  $T_g$  in order to eliminate transformation originating at the free surface. The stable glasses were annealed near  $T_g + 30$  K for various times, after which the transformation was assessed in a temperature ramp (qualitatively as shown in Fig. 1). They observed two glass transitions in the annealed films, with the lower temperature transition associated with the supercooled liquid produced by annealing and a higher temperature transition associated with the stable glass. The higher temperature transition moved to slightly lower temperatures with annealing, which the authors attribute to a partial rejuvenation or softening of the stable glass. Reference 41 reports that the properties of the stable glass can evolve prior to its transformation in the liquid, and at a qualitative level, this matches our observations. Quantitatively, there is an important difference, as we observe annealing-induced changes in the dielectric storage at much earlier stages of the transformation, before there is any shift in the onset temperature. Therefore, we conclude that the apparent softening of the stable glass reported here is distinct from that reported in Ref. 41.

## B. Comparison to simulations

The experimental results have surprising aspects, and we turn to computer simulations for further insights. Simulations based upon the swap Monte Carlo algorithm have reproduced many of the qualitative features of highly stable PVD glasses, including low energy/enthalpy,<sup>23</sup> high density,<sup>39,74</sup> transformation fronts at free surfaces,<sup>75</sup> and a bulk “nucleation and growth” transformation process.<sup>39</sup> Some features of the simulations, such as the velocity of the transformation front, are in quantitative agreement with experiment.

For this comparison, we make use of a two-dimensional system of polydisperse disks that was equilibrated using the swap Monte Carlo algorithm, at a temperature  $T_i = 0.035 \sim T_g/2$ . Constant pressure molecular dynamics simulations are performed starting with these configurations. In a previous work, it was shown that when such configurations are quickly heated to an annealing temperature near  $T_a = 0.1\text{--}1.4T_g$ , transformation occurs via a nucleation and growth process in the bulk.<sup>39</sup> Figure 7 sets the stage for our comparison with the experiments. The upper panel shows how the density of the system evolves at the annealing temperature. The initial drop (at  $t = 10^1$ ) is due to thermal expansion of the glassy solid. The second drop (at  $t = 10^7$ ) is due to transformation to the (less dense) supercooled liquid. The panels at the bottom of Fig. 7 show snapshots of configurations at the very earliest stages of the transformation. Mobile particles are those that have exchanged nearest neighbors and are shown in red. Immobile particles (the stable glass) have retained their nearest neighbors and are shown in blue. The fraction of the system that is liquid is indicated for each snapshot.

Because the simulations provide a high resolution view of the rejuvenation process, we can directly measure the fraction  $x_l(t_w)$  of particles that have already transformed into the supercooled liquid

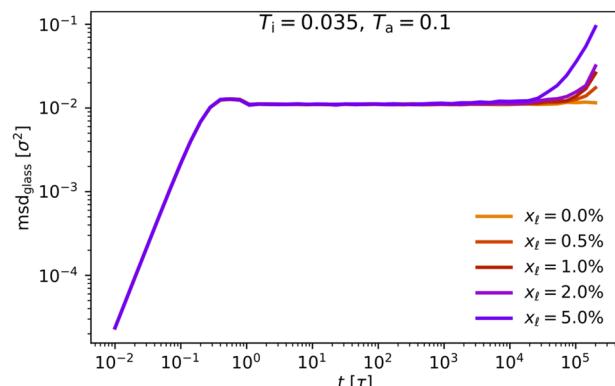

**FIG. 7.** Density as a function of time during the isothermal annealing of a stable computer glass at constant pressure (upper panel). Lower panels: configurations showing immobile particles (stable glass, in blue) and mobile particles (liquid, in red) at three times after the start of annealing, with  $x_l$  indicating the fraction of liquid in the system.

state, by defining mobile particles as those that have exchanged nearest neighbors since the initial condition at  $t_w = 0$ . This fraction is indicated in each snapshot shown in Fig. 7, and we have studied systems for which  $x_l(t_w)$  is smaller than 5%.

For comparison with the experiments, the central issue is whether the properties of the stable glass (blue regions shown in Fig. 7) soften or change in any way during annealing. To this end, we analyze the dynamics of the system starting from selected initial conditions with  $x_l = 0, 0.5\%, 1.0\%, 2.0\%$ , and 5%. We have measured the mean-squared displacement (MSD), as defined in Eq. (1), for these five waiting times, which correspond to  $t_w/(10^6) = 0, 3.06, 3.67, 4.59$ , and 6.12. The measured MSD can be decomposed between liquid and glass particles, corresponding to red and blue particles at time  $t_w$  in the snapshots of Fig. 7. In Fig. 8, for each  $t_w$ , we represent the evolution of the MSD for the glass particles as a function of  $t$ . In this plot, we access the single particle dynamics of the glass particles over a broad range of timescales encompassing the vibrational dynamics at short times and the rejuvenation of the  $\alpha$  relaxation at long times.

It is evident from Fig. 8 that the MSD curves for the glass particles are identical out to times of at least  $10^4$ – $10^5$ , at which point, rejuvenation of the  $\alpha$  process starts and some initially immobile particles start to transform. Crucially, the short-time vibrational dynamics of the glass (including the Boson peak), which can be seen in the time window from  $t = 0.1$  to  $t = 100$  in Fig. 8, is not affected by the emerging liquid regions. Any modification of the glass would affect the peak near  $t \sim 0.5$  or the height of the plateau reached after  $t \sim 10$ .

**FIG. 8.** Mean-squared displacement of stable glass particles as a function time, at various times since the beginning of annealing. The dynamic properties of the stable glass do not evolve with annealing in the simulation.

Further dynamic tests of the simulation results confirm the conclusion that the global dynamics of the system is consistent with a linear superposition of  $x_l$  liquid particles with  $(1 - x_l)$  glass particles, with glass dynamics being insensitive to  $x_l$  over a broad time window. As an example, in the [supplementary material](#) Fig. 10, we show the van Hove function for the glass particles for various values of  $t_w$ . All these simulation tests indicate that the glass regions do not appreciably soften (or change their properties in any manner) prior to the transformation into the liquid. Therefore, based upon the simulations, we reach a conclusion that is apparently inconsistent with the experimental results.

We do not know why the experiments and simulations indicate different conclusions about the softening of the stable glass prior to its transformation, but we will mention some relevant factors. The experiments and simulations utilize similarly stable configurations. The simulations utilized disk-like particles in two dimensions while the experiments studied molecules in three dimensions. We imagine that the difference between molecules and particles may be important. In particular, most real molecules are capable of internal motions, including major conformational changes, which can be important for relaxation dynamics.<sup>48,76–78</sup> In the future, swap Monte Carlo simulations may also be possible with molecular systems, and this would allow a check on this speculation. As a further issue, the limitations of computing power required that a much larger temperature upjump was used in the simulations (roughly threefold) in comparison with the experiments (roughly 10%). This can be appreciated in Fig. 8, where the simulations show about five decades in time between initial cage exploration and stable glass transformation. In the experiments, there is roughly 16 decades in time between these events. This allows the possibility of additional relaxation processes impacting the experiments, possibly explaining the different perspectives given by the experiments and simulations presented here. It will be important for the idea of stable glass softening to be tested with other systems and experimental techniques.

### C. Estimation of characteristic relaxation times of stable deposited glasses

At their deposition temperature, highly stable glasses have such long relaxation times that they cannot be directly measured.

Estimates of these relaxation times vary from  $10^6$  to  $10^{27}$  s,<sup>79–83</sup> depending upon the system and the method used for the estimate. The measurements shown in Fig. 5 provide a new method to estimate these long relaxation times. By making use of the slow initial response of the films to the temperature change, we can extract information about the relaxation times characteristic of the deposited films at the temperature of deposition. We begin this analysis by estimating the initial relaxation times at  $0.98T_g$ . To accomplish this, we fit the changes in onset temperature shown in Fig. 5 to a KWW function with fixed exponent  $\beta = 0.5$ . The  $\tau_{\text{KWW}}$  values increase with the stability of the film, from  $10^3$  s for the  $0.95T_g$  films, to  $10^5$  s for the  $0.90T_g$  films, to  $2 \times 10^7$  s for the  $0.85T_g$  films, and to  $2 \times 10^{10}$  s for the  $0.80T_g$  films. These values are represented by the solid symbols shown in Fig. 9. We interpret this trend as the expected increase in the structural relaxation time with decreasing fictive temperature.

We then employ Tool–Narayanaswamy–Moynihan (TNM) model analysis<sup>20,84,85</sup> to extrapolate the KWW relaxation times down to the deposition temperature, making use of material-specific parameters available from the literature. We use the equation,

$$\ln\left(\frac{\tau_{\text{eff}}}{\tau_0}\right) = \frac{x * \Delta H_{\text{eff}}}{R * T_{\text{meas}}} + \frac{(1 - x) * \Delta H_{\text{eff}}}{R * T_{\text{fictive}}}, \quad (2)$$

where  $\Delta H_{\text{eff}}$  is the effective activation enthalpy based on the local slope of the VFT fit for MMT,<sup>72</sup>  $x$  is the partitioning between the measurement temperature and the fictive temperature, which has been found in the past to be equal to 0.32 for MMT,<sup>72</sup> and  $\tau_0$  is fitted to ensure agreement with the  $\tau_{\text{KWW}}$  values. Since our measurements do not directly access fictive temperature, the fictive temperature for each glass is treated as a constant, equal to the deposition temperature. Based on previous work,<sup>37,73</sup> this is expected to be a good approximation for the two less stable glasses, but it is likely that the fictive temperature is slightly higher for the two most stable glasses. For the most stable glasses (lower deposition temperatures

of  $0.85T_g$  and  $0.80T_g$ ), the mobility at the free surface during deposition is enough to enhance the stability of the deposited film, but not sufficient to fully equilibrate the film.

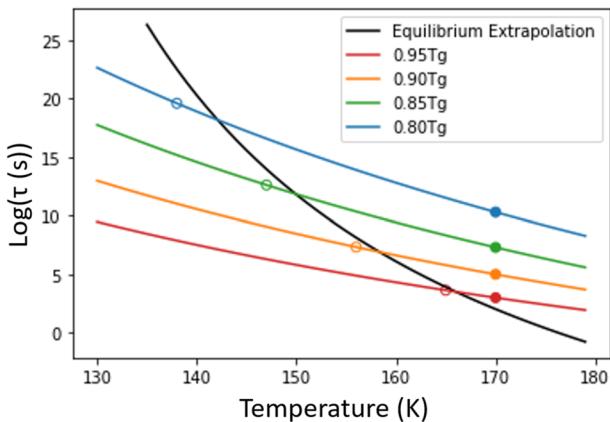

In Fig. 9, we show the  $\tau_{\text{eff}}$  values as a function of temperature, calculated for each glass using Eq. (2); we emphasize that these are “iso-fictive temperature” lines. The open symbols indicate the estimated value of  $\tau_{\text{eff}}$  at the deposition temperature. As shown in Fig. 9, the predicted  $\tau_{\text{eff}}$  value for the  $0.95T_g$  glass is very close to that expected (by extrapolation) for the equilibrium supercooled liquid at that deposition temperature. Similarly, the  $\tau_{\text{eff}}$  value for the  $0.90T_g$  glass is close to the value expected for the supercooled liquid. These results are consistent with the view that the VFT temperature dependence of  $\tau_\alpha$  above  $T_g$  provides a reasonable prediction of  $\tau_\alpha$  down to  $0.90T_g$ .

For the lower deposition temperatures, there is an increasing deviation of the calculated  $\tau_{\text{eff}}$  value from the VFT-predicted equilibrium relaxation times. This could be interpreted in two ways. First, that the equilibrium relaxation times do not follow the VFT temperature dependence at these lower temperatures. Second, that the films prepared at lower deposition temperatures do not have the same relaxation times as the equilibrium supercooled liquid would at those same temperatures. Since we are fairly confident that the fictive temperatures of these more stable films are not actually equal to the deposition temperature, we lean toward the second interpretation. This does not, however, rule out the possibility that the equilibrium relaxation times below  $0.90T_g$  follow a different temperature dependence than the VFT functional form observed at higher temperatures.

## V. CONCLUSION

In conclusion, by annealing vapor-deposited glasses of MMT slightly below  $T_g$ , we are able to observe at least the initial stages of rejuvenation into the supercooled liquid. From changes in the onset temperature during annealing, we draw inferences about the relaxation times of glasses of different stabilities. These relaxation times are extremely long for the most stable glasses, as expected from previous experiments where annealing was performed above  $T_g$ . From changes in the storage component of the dielectric susceptibility, we provide insight about the recovery of the boson peak during annealing. We infer from these experiments that the boson peak recovers more quickly than the transformation of stable glass into supercooled liquid. This would indicate that the properties of the stable glass are evolving prior to its transformation.

We also performed computer simulations to mimic the experimental annealing experiments, starting with ultrastable configurations generated by using the swap Monte Carlo method. In the computer simulations, the properties of the stable glass do not evolve prior to transformation, in contradiction with the experimental work. This is surprising given the close correspondence between experimental PVD glasses and swap glasses that has been documented in a previous work. Clearly additional experiments and simulations are needed to resolve the question of whether stable glass properties evolve during annealing. One possible approach would be to more directly observe the evolution of the boson peak with neutron or Brillouin light scattering experiments. It would also be useful to perform experiments similar to those reported here on additional

**FIG. 9.** TNM analysis of  $\tau_{\text{eff}}$  values for glasses of different stabilities (KWW fits from Fig. 5, shown here as the solid circles at 170 K) to estimate the relaxation time of each stable glass at the deposition temperature, shown by the hollow circles at the deposition temperature for each iso-fictive temperature line of relaxation times. Extrapolated equilibrium relaxation times are based on a VFT function from the literature.<sup>72</sup>

molecular systems. Simulations on stable molecular glasses would be particularly useful.

## SUPPLEMENTARY MATERIAL

Information regarding calibration experiments, fitting procedures, and figures showing agreement of additional data from the experiments shown in the main manuscript are available in the online [supplementary material](#).
